Abstract

Ion-induced damage and intermixing was evaluated in InGaN/GaN multi-quantum wells (MQWs) using 35 keV N\textsuperscript{+} implantation at room temperature. \textit{In situ} ion channeling measurements show that damage builds up with a similar trend for In and Ga atoms, with a high threshold for amorphization. The extended defects induced during the implantation, basal and prismatic stacking faults, are uniformly distributed across the quantum well structure. Despite the extremely high fluences used (up to $4 \times 10^{16}$ cm$^{-2}$), the InGaN MQWs exhibit a high stability against ion beam mixing.

Keywords: ion beam mixing, InGaN, quantum wells, implantation

(Some figures may appear in colour only in the online journal)

1. Introduction

InGaN/GaN multiple quantum wells (MQWs) are the basis of many modern optoelectronic devices, including bright light emitting diodes, laser diodes, light displays, solar cells, etc. However, the strain induced by the lattice mismatch, in addition to the spontaneous polarization in III-N heterostructures, affects the internal quantum efficiency through the so-called quantum-confined Stark effect (QCSE), which induces a spatial separation of electron and hole wavefunctions [1], in particular for high InN-content devices, with wide MQW emitting in the green spectral region. One of the strategies suggested to mitigate QCSE in GaN-based materials is the fabrication of intermixed or graded quantum structures by ion beam mixing [2, 3]. This approach has been successfully applied in AlGaAs/GaAs [4, 5], AlGaInP/GaInP [6] and MgZnO/ZnO [7] MQWs, but it remains unexplored in InGaN/GaN systems.

Despite the outstanding radiation resistance of GaN (with amorphization thresholds above 10 displacements per atom), recent experimental results in GaN/AlN MQWs [8] have proved that partial intermixing can be induced at low temperatures (15 K) for sufficiently high Ar fluences. This intermixing induced by collision cascades was shown to be...
more efficient than thermal interdiffusion [8], and motivates the present studies. We consider here conventional InGaN/GaN nanostructures under more adaptable conditions for industrial scalability, i.e., room temperature implantation with native ions. Thus, in this work we investigate the damage build-up during ion mixing processes in InGaN/GaN MQWs with 35 keV N⁺ ions, comparing the behavior with thick InGaN layers.

2. Experiment

The In₉Ga₁₋₉N/GaN MQW sample was grown by metal-organic chemical vapor deposition on a (0001) GaN/sapphire template [9]. The active layers consist of five In₉Ga₁₋₉N/GaN periods with thicknesses of 3 nm/20 nm (measured by transmission electron microscopy (TEM)) and an average InN molar fraction in the QWs of x = 10% (determined by Rutherford backscattering spectrometry (RBS)). A ~20 nm GaN capping layer was deposited to protect the active layers. Photoluminescence and ionoluminescence measurements reveal a green QW emission centered at ~530 nm (2.34 eV).

Ion implantation and in situ RBS in channeling mode (RBS/C) studies were carried out in the double-beam chamber at the Institut für Festkörperphysik (Jena) [10]. The implantations were performed at room temperature with 35 keV N⁺ ions, being the energy selected to place the maximum of the damage profile in the central region of the MQWs. According to Monte Carlo simulations with the SRIM code the mean N range is 55 nm, with a longitudinal straggling of 25 nm [11]. The ion fluence was increased sequentially from 5 × 10¹² to 4 × 10¹⁶ cm⁻² and the sample was tilted by 7° off-axis during the implantation to avoid channeling effects. After each implantation step, the damage accumulation was evaluated in situ by RBS/C spectra of the sample using a 2.2 MeV He⁺ collimated beam (~1 mm²). RBS/C spectra were taken in the (0001) aligned direction, using a 3-axis goniometer for sample orientation.

The final as-implanted sample, corresponding to a total fluence of 4 × 10¹⁶ cm⁻², was further studied ex situ with x-ray diffraction (XRD), TEM, and grazing incidence RBS. XRD data were acquired in a D8Discover high resolution diffractometer (Bruker-AXS) radiation, an asymmetric two-bounce Ge(220) monochromator, and a NaI scintillation detector. To reduce the divergence, the incoming x-ray beam is collimated with a 0.2 mm slit while the diffracted beam is collimated with a 0.5 mm motorized slit and a 0.1 mm fixed slit, being the approximate final 2θ/ω angular resolution ±0.01°. XRD 2θ/ω curves were simulated using the dynamical theory of XRD [12] The influence of the implantation is taken into account by including the static Debye–Wallner parameter (describing the attenuation caused by thermal motion) on the structure factor of individual layers, thus attenuating the derived intensity and considering a c-lattice expansion following the work of Boule and Debelle [13].

TEM experiments were carried out using a JEOL 2010F microscope operated at 200 kV. Structural and compositional features were studied from micrographs collected by HR-TEM and high angle annular dark field (HAADF) imaging in scanning-TEM (STEM) mode, while nanoprobe analyses of local proportions of atomic elements were based upon energy dispersive x-ray spectroscopy done in the same mode (EDX-STEM). Grazing incidence RBS experiments were carried out with a 2 MeV He⁺ beam using the Van de Graaff accelerator at LATR/IST (Portugal).

3. Results and discussion

Figure 1(a) shows RBS/C spectra of the sample after the implantation to different total N fluences. Remarkably, the In signal does not show any shift to higher energies even for the highest fluence, what confirms that there is neither appreciable diffusion of In towards the surface, nor significant energy dispersive x-ray spectroscopy in the MQWs and avoiding the surface peak zone. The minimum yield (χₘᵟᵣᵣ), determined as the ratio of the aligned and the random backscattering yield, was obtained for both windows. The increase of χₘᵟᵣ with fluence determines the damage accumulation. The damage level is then described as the difference in the minimum yield of the implanted and virgin sample, Δχₘᵟᵣ = χₘᵟᵣ(implanted)−χₘᵟᵣ(virgin). As a reference, the initial χₘᵟᵣ values for the as-grown sample were 4.4 (1)% and 2.2(1)% for In and Ga, respectively. For the maximum fluence of 4 × 10¹⁶ cm⁻² the aligned level almost overlaps with the random level (χₘᵟᵣ = 100%), indicating a level of damage that is maximal for measurement by RBS/C.

Figure 1(b) shows the damage level obtained for In(ω₁) and Ga(ω₂) for the entire range of fluences. Both curves have a similar behavior in two main regions of interest. For low fluences (<10¹⁵ cm⁻²), damage builds up continuously but the damaged fraction remains below 4%. The slowing down of damage accumulation, here occurring for fluences between 10¹⁵ and 10¹⁶ cm⁻², is typical of materials with strong dynamic annealing [14]. In GaN films implantation damage in this low fluence regime is characterized by the formation of small point defect clusters and low concentrations of stacking faults, while for higher fluences larger defect clusters form, including extended defects such as stacking faults [15]. Figure 1(b) shows a strong increase of damage level for fluences above 10¹⁵ cm⁻² which we attribute to the formation of stable defect clusters and extended defects.

In general, the damage build-up curve for the InGaN MQW is qualitatively similar to those reported by Kucheyev et al and Wendler et al for gold implantation at low [16] and room [14] temperature, included in figure 1 as references. Both In and Ga show the same trend, but the damage accumulation for Ga appears to be systematically lower. This agrees with previous experiments in thin InGaN films, which have also shown similar levels of damage build-up for the In- and Ga-sublattice, but where a significantly higher resistance was found for GaN than for InGaN, even for very small amounts of InN [14, 16].
Solid lines in figure 1(b) represent the fits using Hecking’s model, which takes into account the production ($P_{pd}$), recombination ($R_{pd}$), and clustering ($C_{pd}$) of point defects in semiconductors, as well as the production of amorphous regions ($P_a$) and their growth ($G_a$) [17, 18]. The results obtained from these fits are summarized in Table 1. The variations observed with the values obtained from Wendler et al [16], in particular the low values of $P_a$ obtained here, are ascribed to the different temperature and not to the thickness or the structure of the InGaN layers. This is supported by the fact that the damage build-up curve does agree well with the data from Kucheyev et al [14] at room temperature, pointing out the relevant role of dynamic annealing processes.

Figure 2(a) shows the XRD $2\theta/\omega$ scans for as-grown and as-implanted ($4 \times 10^{16}$ cm$^{-2}$) MQWs. (b) and (c) Reciprocal space mappings for both samples. The color bar represents intensity in a log scale.

variation of layer thicknesses (up to 0.7 nm deviation from the nominal structure) and a decreased Debye–Waller factor (∼0.5 for the first three periods increasing until reaching again unity for the deeper layers). Furthermore, a deformation of the implanted layers was taken into account yielding a perpendicular strain of maximum ∼1% for the first three periods and decreasing to zero for the deeper unimplanted layers.

The in-plane ($Q_x$) and out-of-plane ($Q_z$) components of the scattering vector were obtained from the corresponding (1015) reciprocal space maps of both samples, shown in figures 2(b) and (c). In addition to the broadening, the maps confirm the strong suppression of the SL peaks (the signal above GaN being due to the remaining $K_{\alpha 2}$ contribution from the monochromator). The elongated peak below GaN is associated to the expansion of the $c$-lattice parameter in the heterostructure, an effect well-documented for implantation in thin nitride films [19, 20]. It should be noted that the dynamical theory may not be well suited to describe XRD of the highly damaged sample after high fluence implantation. Nevertheless, the results are in good agreement with the RBS and TEM results presented in this paper suggesting a deterioration of the crystal quality, in particular of the first three periods, while intermixing remains below the detection limits of the employed techniques.

Figure 3 shows TEM images of the defects formed in the as-implanted maximum-fluence sample. Dark field images, recorded using 0002, 1–120 and 1–100 reflection $g$ vectors, respectively (figures 3(a)–(c)), reveal a heavily damaged surface region. Figure 3(a), taken under the $g = 0002$ condition, indicates the presence of a large number of point defect clusters, interstitials or vacancies, also confirmed in figure 3(b). Figure 3(c), exciting the $g = 1$–100 reflection, shows that, in addition to the defect clusters, a complex network of basal stacking faults (BSFs), both intrinsic ($I_1$ and $I_2$ type) and extrinsic ($E_1$, and prismatic stacking faults [21, 22] has been generated during the implantation. A high resolution example of one $I_2$ BSF inside the implanted region is exhibited in figure 3(d). The formation of these extended defects agrees well with previous reports on both GaN [15, 19] and InGaN [23], where clusters and planar defects have been pointed out for relatively high implantation fluences. A similar defect structure of the ternary and binary compounds can explain the homogenous distribution of
defects observed in the present case, where the presence of the QWs does not seem to affect the defect distribution and the migration/annihilation properties.

Figure 4 shows HAADF micrographs of (a) the as-grown and (b) the as-implanted samples. After the implantation, the top first QWs are not clearly distinguishable due to the high damage levels, which are known to distort the unit cell either by accumulation of point defects or strain fields associated with extended defects, both cases disimprove on the contrast of HAADF-STEM images [24, 25], and can render the direct interpretation of contrasts in terms of chemical compositions ineffective. However, local EDX spectra reveal that most of the In remains close to the original QW structure (not shown). This fact was confirmed by grazing incidence (60° tilt between the surface normal and the incoming beam) RBS measurements, which clearly resolve the first two InGaN QWs which are completely separated in the spectrum. Figure 4(c) directly compares the RBS spectra of the as-grown and as-implanted sample; no major difference can be discerned. Both spectra are compatible with the targeted original depth profile. Nevertheless, some degree of intermixing cannot be completely excluded due to the limited depth resolution of the technique. These results differ from those obtained for AlN/GaN MQWs where a partial intermixing can be induced by 100 keV Ar+ implantation [8]. This fact might be related to the different efficiency of the ballistic intermixing in both cases (which is expected to be three times lower in the current study due to the lower energy and ion mass) but other factors such as the electronic energy-loss contribution, the stress state of the material, and the solubility limits of the elements cannot be ruled out and could also play a role in this regard.

4. Conclusions

We have demonstrated that InGaN/GaN MQWs exhibit a high resistance to ion beam induced mixing at room temperature. Damage builds up with a similar trend for In and Ga atoms, leading to the formation of defect clusters and extended planar defects. Such defects are homogeneously distributed throughout the MQWs, but despite the high damage level attained both EDX-STEM and grazing incidence RBS confirmed that compositional intermixing in the QWs remains low.

Acknowledgments

We thank Dr P Ruterana for fruitful discussions and suggestions. We acknowledge support by FCT Portugal (bilateral project DAAD/FCT 2011-2012, PTDC/FIS-NAN/0973/2012, SFRH/BPD/74095/2010, Investigador FCT) and Juan de la Cierva (under contract number JCI-2012-14509). TEM experiments were carried out in the Electron Microscopy-DME- and Sample Preparation-LPM- Divisions of the Central Services of Science and Technology of the University of Cádiz (SCCYT-UCA), being financed by the projects MAT2010-15206 (CICYT, Spain), EU-COST Action MP0805, and P09-TEP-5403 (Junta de Andalucía with EU-FEDER participation).
